The cardinality of a set containing the pairwise sums of four integers

Wouter van Doorn

Abstract

Choi, Erdős and Szemerédi proved the existence of a constant c such that for any set $A \subseteq \{1, 2, ..., 2n\}$ with $|A| \ge n + c$ there exist four integers b_1, b_2, b_3, b_4 with $b_i + b_j \in A$ for $1 \le i < j \le 4$. We show that one can take c = 41285.

1 Introduction

For an integer $k \geq 3$, let $g_k(n)$ be the smallest integer such that for all sets $A \subseteq \{1, 2, \ldots, 2n\}$ with $A \geq n + g_k(n)$, one can find distinct integers b_1, b_2, \ldots, b_k (not necessarily contained in A) with $b_i + b_j \in A$ for $1 \leq i < j \leq n$. Choi, Erdős and Szemerédi introduced this function in [1], and proved many bounds on it. For example, they proved $g_3(n) = 2$, $g_4(n) \leq c$ for some constant c, $c_1 \log(n) < g_5(n) < c_2 \log(n)$ for some constants c_1, c_2 and $c_3\sqrt{n} < g_6(n) < c_4\sqrt{n}$ for some constants c_3, c_4 . They did not necessarily attempt to optimize all these constants however, and estimating the value of $g_k(n)$ is listed as problem #866 at [2]. In this short note we will (without claiming much originality ourselves) revisit their proof that $g_4(n)$ is bounded, and find an explicit value for it.

2 An explicit upper bound

The goal is to find an explicit value of c in the theorem of Choi, Erdős and Szemerédi.

Theorem 1. Let c be equal to 41285. If $A \subseteq \{1, 2, ..., 2n\}$ is any set with $|A| \ge n+c$ elements, then there exist distinct integers b_1, b_2, b_3, b_4 with $b_i+b_j \in A$ for $1 \le i < j \le 4$.

In order to be able to prove this, we need a few lemmas, the first of which will essentially be the base case of Lemma A in [1].

Lemma 1. Let $y_1 < y_2 < \ldots < y_t$ be a sequence of integers and set $y := y_t - y_1$. If $t \ge y^{1/2} + y^{1/4} + 2$, then there exist integers x_1, x_2, x_3 with $x_2 \ne x_3$ such that $x_1, x_1 + x_2, x_1 + x_3, x_1 + x_2 + x_3$ are all elements of the sequence. That is, the sequence contains all subset sums containing x_1 .

Proof. If an integer m and distinct indices i_1, i_2, j_1, j_2 exist with $y_{j_1} - y_{i_1} = y_{j_2} - y_{i_2} = m$, then one can choose $x_1 = y_{i_1}, x_2 = y_{i_2} - y_{i_1}, x_3 = m$. However, if such an m and indices do not exist, then the sequence forms a so-called Golomb ruler; a sequence whose pairwise differences are all distinct. For such a sequence we must have $t^2 - 2t\sqrt{t} < y$, by Theorem 4.9 in [3, p. 32], but one can check that this inequality contradicts the assumption $t \ge y^{1/2} + y^{1/4} + 2$.

We will use the previous lemma to prove what is essentially the induction step of Lemma A in [1].

Lemma 2. Let $y_1 < y_2 < \ldots < y_t$ be a sequence of integers and set $y := y_t - y_1$. If $t \ge \sqrt{2}y^{3/4} + y^{1/2} + 1$, then there exist integers x_1, x_2, x_3, x_4 with x_2, x_3, x_4 distinct such that the sequence contains all subset sums containing x_1 .

Proof. There are a total of $\frac{1}{2}t(t-1)$ differences $y_j - y_i$ in the interval [1, y-1]. Since one can check that inequality $\frac{1}{2}t(t-1) > y(y^{1/2} + y^{1/4} + 2)$, this implies there is an integer m that can be written in more than $t' := y^{1/2} + y^{1/4} + 2$ different ways as a difference $y_{j_1} - y_{i_1} = y_{j_2} - y_{i_2} = \dots = y_{j_{t'}} - y_{i_{t'}} = m$. Now we apply Lemma 1 to this sequence $y_{i_1}, y_{i_2}, \dots, y_{i_{t'}}$ to obtain x_1, x_2, x_3 , and set $x_4 = m$.

As in [1], the previous lemma can be used to deduce the existence of integers whose pairwise sums are contained in A, if A contains sufficiently many even integers.

Lemma 3. Let $y_1 < y_2 < \ldots < y_t$ be a sequence of even integers and set $y := y_t - y_1$. If $t \ge \sqrt{2}y^{3/4} + y^{1/2} + 1$, then there exist distinct integers b_1, b_2, b_3, b_4 such that the sequence contains all pairwise sums $b_i + b_j$ with $1 \le i < j \le 4$.

Proof. Apply Lemma 2 with
$$b_1 = \frac{1}{2}x_1$$
 and $b_i = \frac{1}{2}x_1 + x_i$ for $2 \le i \le 4$.

We are now ready to prove our main result.

Proof of Theorem 1. With t the number of even elements of A, we trivially have $t \ge c$. Let us first assume that there are no even elements of A contained in the interval [4t + 4, 2n - 4t - 4].

In that case, there are either at least $t':=\left\lceil\frac{1}{2}t\right\rceil$ even elements of A in [2,4t+2], or at least t' even elements of A in [2n-4t-2,2n]. In either situation, with y=4t+2 we have an interval of length y with t' even elements. If we can prove $t'>\sqrt{2}y^{3/4}+y^{1/2}+1$, then we are done with this case by Lemma 3. But this follows from the (in)equalities $t'=\left\lceil\frac{1}{8}(y-2)\right\rceil=\left\lceil\frac{1}{2}t\right\rceil\geq 20643$ and the fact that $\left\lceil\frac{1}{8}(y-2)\right\rceil>\sqrt{2}y^{3/4}+y^{1/2}+1$ holds for all $y\geq 20643$.

We may therefore freely assume the existence of an even element $2m \in A$ with $2t+2 \le m \le n-2t-2$. Now let (x_i,y_i) be a pair of odd integers in the interval I:=[m-4t-2,m+4t+2] with $x_i < y_i$ and $x_i+y_i=2m$. With b_1,b_2 even integers with $b_1+b_2=2m$ and $m-2 \le b_1 < b_2 \le m_2$, we have $x_i+b_1 \ge m-4t-2+m-2=0$ for all x_i , which implies $x_i+b_1 \ge 1$ as this sum is odd. On the other hand, $y_i+b_2 \le m+4t+2+m+2=2m+4t+4 \le 2n$. Since we have 2t+1 distinct pairs (x_i,y_i) in I, while A misses t-c < t odd integers in the interval [1,2n], there must be a pair (x_i,y_i) in I such that $b_1+x_i,b_2+x_i,b_1+y_i,b_2+y_i$ are all in A. We can then take $b_3=x_i,b_4=y_i$. \square
